ABSTRACT

Chronic kidney disease (CKD) is a life-threatening condition originated from renal dysfunction. So far we do not have perfect remedies and therefore prevention of progression draw high interests from both researchers and clinicians. There are a lot of risk factors for its development and its prognosis, among them, hypertension and diabetes are the most common risks. We have been using biomarkers for diabetes and hypertension such as HbA1c, diurnal changes of blood pressure, morphological changes in blood vessels and cardiac functions. Recent advances in chemical analysis proposed several biomarkers from blood and urine samples, such as microalbuminuria, L-FABP and others. Animal and cell experiments also suggest potential biomarkers, however, they are not necessarily applicable in human. Besides those chemical markers, studies on genetic or epigenetic factors such as microRNA have been reported. In addition to those upcoming techniques, we learned a lot from classical cellular morphological examination of urinary sediments.

In the current review, we focus on podocyte and round cell in the urinary sediment and epigenetic markers in the urine as novel biomarkers for CKD and its risk factors those are hypertension and diabetes.

Introduction

Concept of chronic kidney disease (CKD) is widely accepted, since it is a risk factor for end-stage renal disease (ESRD) and cardiovascular disease. Diabetes mellitus and hypertension are the leading cause of CKD. In Japan, approximately 13% of the Japanese adult population is estimated to have CKD[1]. In the current situation there is no curative treatment for CKD, there is an urgent need to prevent its onset and progression. However, renal lesion assessment for diagnosis and prognosis currently can only be evaluated by renal biopsy. Renal biopsy is an invasive test that requires hospitalization and is difficult to repeat. Since patients with renal disease have few subjective symptoms, they tend to hesitate when it comes to renal biopsy, which leads to interruption of hospital visits without scrutiny.

Urinalysis has very long history back to 2000B.C. in India. Urine, as an easily accessible biological fluid, offers a unique opportunity for monitoring disease progression and prognosis. Advances in technologies for analyzing urinary protein and various substances in urine have revealed the existence of substances related to the diagnosis and prognosis of kidney diseases. In acute renal injury (AKI), the expression of molecules such as Kim-1 and NGAL have been confirmed in the renal proximal tubular epithelial cell, and the importance of L-FABP as a biomarker for the progression of renal injury are also attracting attention. However, most of them reflect renal tubular cells injuries [2], targeting the glomerular injury, nothing exceeds the conventional total protein or albumin excretion, but these are not specific to glomerular injury as they are also resorbed at tubules. Therefore, it is necessary to establish a urinary biomarker that can diagnose glomerular disease and estimate renal prognosis. In addition to these chemicals, cellular components in the urinary sediment has been studied for more than 100 years. Red blood cells, white blood cells and casts were reported from the beginning and recently we and other researchers reported that podocyte, inflammatory cells such as neutrophils and macrophages, round cells in the urine can be biomarkers for glomerular and tubular damages. And by applying molecular biology, investigation of urinary exosomes, analysis of cellular epigenome markers, it become possible to determine epithelial cell origin in the kidney as well as novel biomarkers such as microRNA, cell-derived proteins. and those are reported to be related to CKD prognosis.

By multimodal approaches in help of machine learning, it is expected that combining urinary cellular markers with clinical parameters (e.g., blood pressure, glycemic control) improves prognostic accuracy. And algorithms help integrate large biomarker datasets for personalized risk stratification.

In the current review, we focus on recent advances in cell components in the urine that is expected to be good markers for CKD, especially in diabetic and/or hypertensive patients

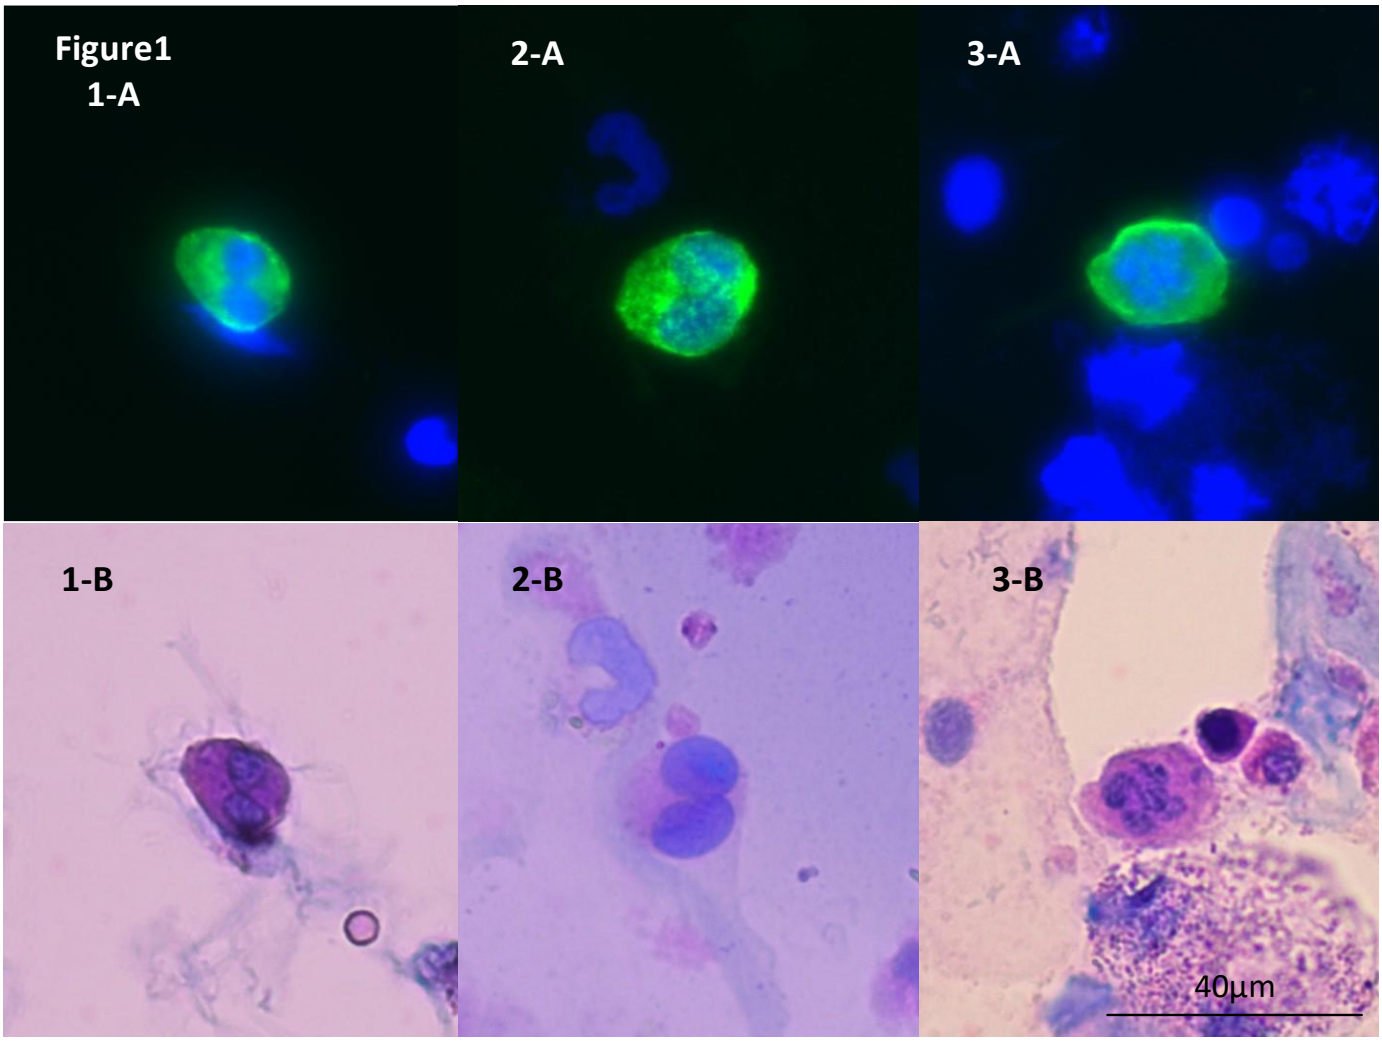

Figure 1: The representative images of urinary podocytes. A: Immunofluorescence staining. B: Sternheimer staining after immunofluorescence staining in the same sample.

It has been indicated that podocyte injury leads to clinical development of proteinuria and the pathological progression of glomerulosclerosis. Research indicates that podocyte detachment, leading to their presence in urine, is associated with glomerular damage in CKD. Elevated urinary mRNA levels of podocyte-associated genes, such as NPHS2 (podocin) and PODXL (podocalyxin), have been observed in patients with progressive diabetic nephropathy, suggesting their potential as biomarkers for disease progression[3-6]. However, these markers are mRNA level or podocyte-derived microparticles and difficult to use them in routine clinical work. On the other hand, the detection of podocytes in urinary sediment by an immunofluorescence staining using an antibody to podocalyxin and the number of podocyte relates with prognosis of CKD [7-10]. In comparison between immunostaining and Sternheimer staining[11], we characterized podocyte morphology. The size varies from 10 to 40 µm and round-shaped. The bi- or multi-nuclei cells are observed and nucleus localize unevenly. When cells are smaller, the cytoplasm is thicker and vice versa. The surface of cytoplasm is smooth and fine structure. The margin of cytoplasm is clear but in some part is obscure. Cytoplasm is stained deep-purple to light pink and when it is thick, stained in purple. It was considered that the greatest feature of podocytes was to show a very smooth and fine cytoplasmic surface structure regardless of cell size / thickness / shape, nucleus size / shape / number, and stainability (table1).

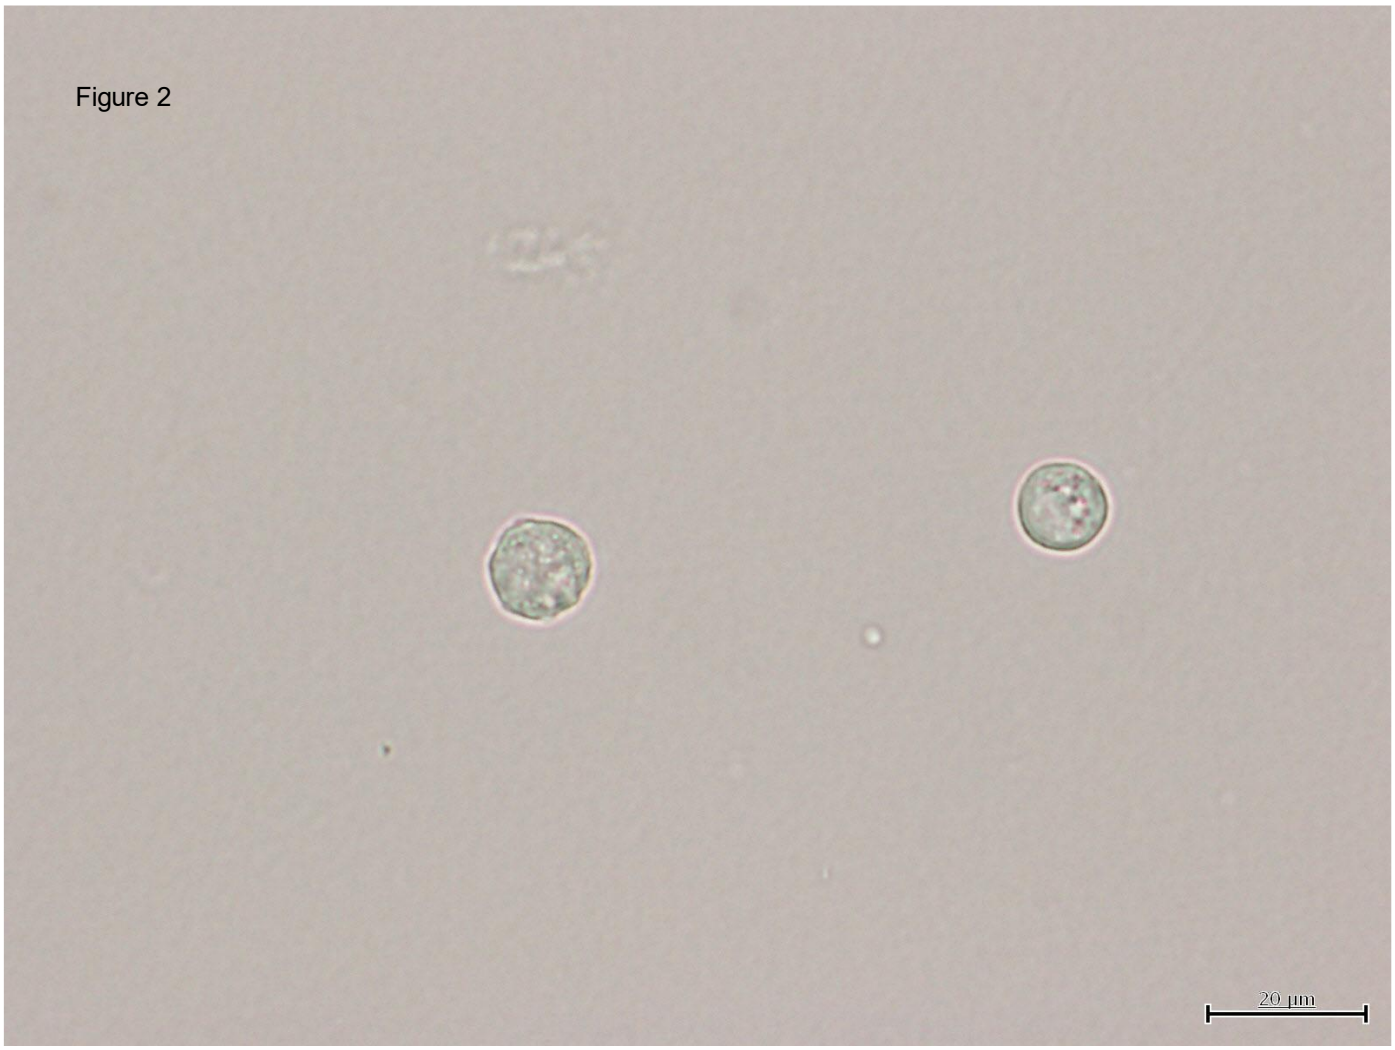

Figure 2: Non-stained picture of round cell

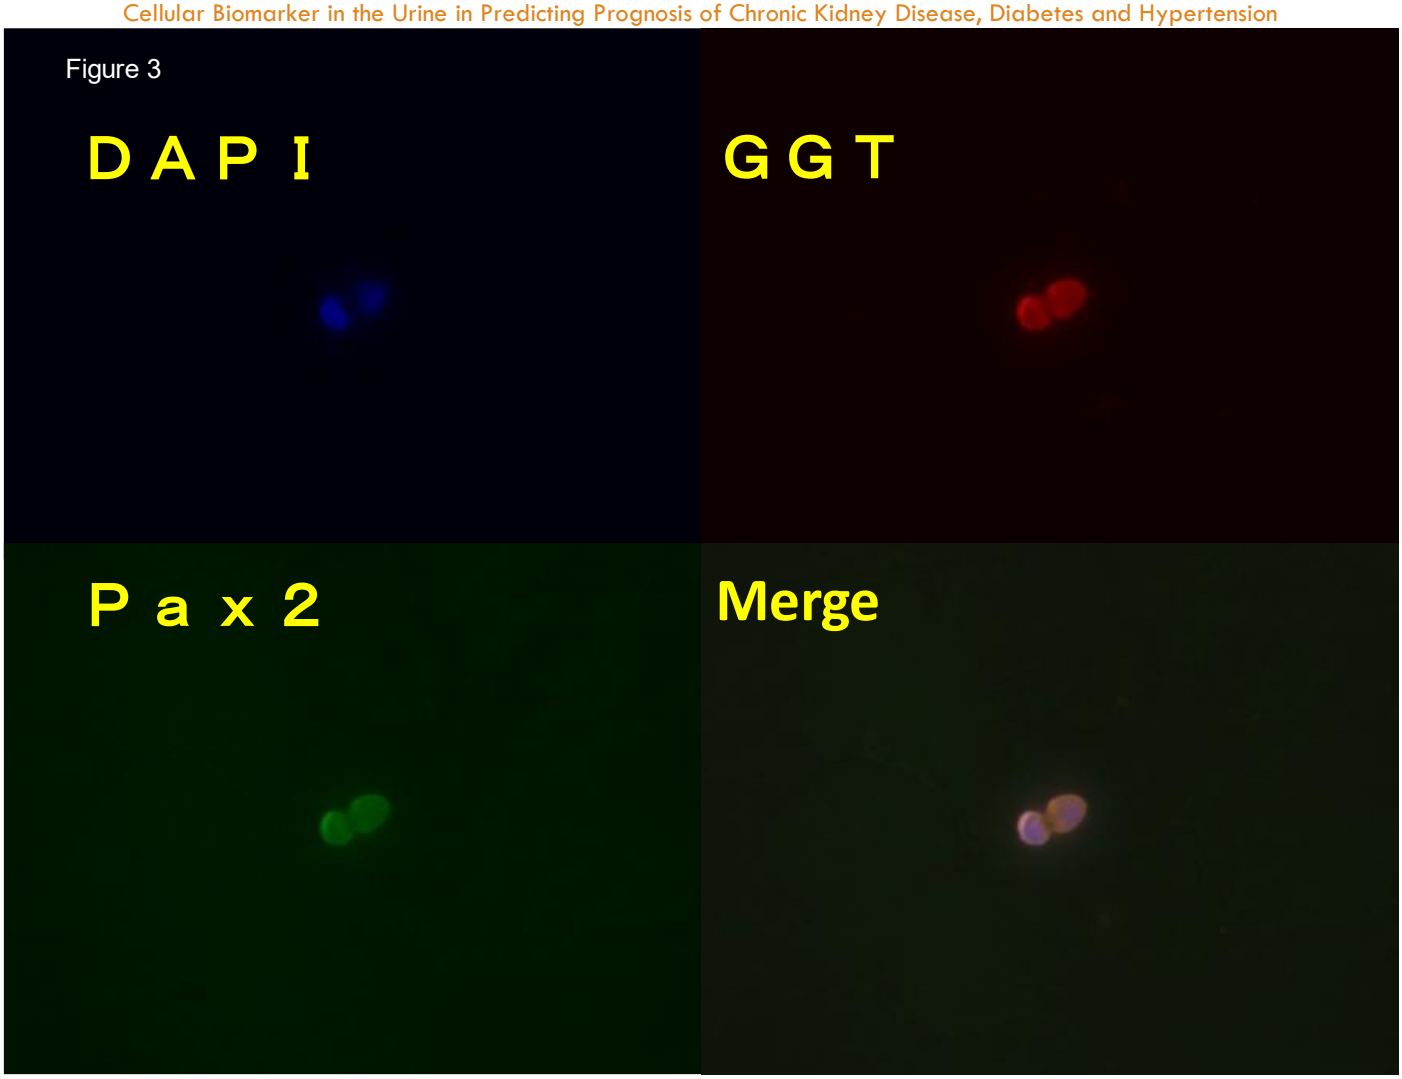

Figure 3: Immunostaining of round cell
Round cell is positive for GGT and Pax2 a marker of epithelial cells and undifferentiated cells respectively.

Figure 4: Round cell can be found in urinary cast, suggesting that the cell is derived from either glomerulus or tubules but not from ureter or lower urinary tract.

Round cell in the urine sediment was first reported by us[12]. It is characterized as a cell about 10μm in diameter and nuclear/cytoplasm ration is large. Its molecular markers are PAX2, HOX11, OSR1, WT1 and SIX2 which suggests the round cell is undifferentiated. and negative for podocalyxin. and when it is cultured, it differentiates into epithelial cell and positive for GGT-1 (Figure 2). Round cell number correlate with the prognosis of renal function and predict risks for hemodialysis in CKD patients. Prospective study shows in severe CKD patients, area under the curve of receiver-operated characteristic (ROC) curve in round cell number is better than urinary protein. The round cell is also found in hyaline casts, that suggests the cell are originated from tubules but not from urinary tract. In contrast to podocyte, which can not be divided and regenerate in the glomerulus and podocyturia suggests podocyte injury, renal tubules are regenerated rapidly and actively and in urine sediment we observe a lot of differentiated tubular epithelial cells. In order to regenerate tubules, there must be progenitor cells. We assume that this round cell is a progenitor cells and healthy kidney can recruit the round cell to the injured tubular lesion and it can differentiate into epithelial cells but under disease condition, the cell fail to home to the lesion and drop into the urine. Therefore, the number of round cell reflects tubular condition and/or progenitor cell condition and can be a biomarker to predict renal dysfunction.

Recent preliminary study shows that in hypertensive nephropathy, round cell number increases and it is independent from proteinuria and can be used as tubular damage marker.

Table: Epigenomic markers

	The cellular findings in Sternheimer stain
Shape	Various shapes, round-shape
Nucleus	The bi- or multi- nuclei cells are observed and nucleus localize unevenly.
Size	10μm～40μm
Thickness of cytoplasm	Regarding the thickness of the cytoplasm, the identified cells tended to be thicker as the cell size was smaller and thinner as the cell was increased, but this could not be said unconditionally
Structure of cytoplasmic surface	A very smooth and fine cytoplasmic surface structure
Structure of cytoplasmic edges	Clarity
Stainability	A red purple of a light pink.

Components of kidney cells are proliferating and regenerating continuously except for podocyte. Diabetic kidney disease, hypertension-related kidney damages or CKD are all involved in all the cell components, however, widely used biomarkers are GFR and proteinuria which mainly reflect glomerular damages and information on tubular cells are limited such as Kim-1, NGAL and L-FABP1. In addition, the condition of regeneration could not be monitored so far. As mentioned above, round cell is one marker of regeneration. Genetical markers, specially epigenomic markers could reflect cellular proliferation and kidney regeneration. Epigenetic markers refer to modifications in DNA, histones and microRNAs that regulate gene expression without changing the underlying genetic sequence. In urine, exosomes contain microRNAs and exosomes are studied widely. Among them, some microRNAs are related with inflammation, fibrosis (miR-21, -155, -29), hypertension (miR143/145, -210) and diabetes (miR-375, -9, -29)[13-15]. Several aberrant DNA and histone modifications are also observed in mesangial cells as well as leukocyte and its relation with diabetic kidney disease prognosis [16-25]. From the study of hypertensives, DNA damages and DNA methylation are reported to correlate with renal prognosis [26]. In addition to those gene-expression-related markers, we reported DNA methylation pattern can characterize urinary cell from sediment. By using this technique, DNA methylation pattern can quantify proximal tubules in urine and it closely relate with diabetic kidney disease status and prognosis[27,28].

Regarding to hypertension and renal function and damages, we cannot avoid discussing salt-induced hypertension. Hypertensives can be divided into two phenotypes, salt-sensitive and salt-resistant, the former phenotype is represented by primary aldosteronism and the latter is by pheochromocytoma. Salt-sensitive hypertensives raise their blood pressure in parallel with salt intake[29] and its prognosis is poorer than salt-resistant even if the blood pressure is controlled to the same level[30]. Some genetical causes of salt-sensitive hypertension is reported, however, in most of the cases, the phenotype is affected by environmental factors[31]. It is well accepted the regulation of sodium channels plays a pivotal role in salt-sensitive hypertension. As mentioned above, salt-sensitivity is reversible and epigenetical regulation of sodium channel can be a plausible cause of salt-sensitive hypertension. We and others reported that histone [32] methylation and NCC activation or DNA methylation alters epithelial sodium channel (ENaC) activation [33] directly or via central renin-angiotensin system[32-34] to cause salt-sensitive hypertension. These markers can be a biomarker for salt-sensitive hypertension if it can be measured in urine or in leukocyte.

Urine sediment is a powerful tool to find biomarkers closely related with kidney. Proximal tubules are the longest and most abundant cell in the sediment. Proximal tubular dopamine receptor is also a physiologically important factor for salt-sensitivity and isolating RPTCs from urine provides a personalized cell-based diagnostic test of salt-sensitivity[35]. NCC and ENaC alpha is also quantified in cultured cells from urine sediment[36,37]. Besides these cell analysis, urinary microsomes also provide us candidate markers for salt-sensitivity[38]. These studies are carried out in single group and validation studies are required.

Conclusion

CKD affects millions of people worldwide, making it a widespread health concern. It often goes undiagnosed in its early stages because symptoms can be subtle or absent. With early detection through screening, CKD can often be managed or even prevented from progressing to more severe stages. Lifestyle changes, medications, and regular monitoring can help maintain kidney function and reduce complications. Current biomarkers are not high enough in both sensitivity and specificity. By multimodal approaches, including chemical, genetical, and epigenetic markers as well as cell population in the urine sediment will provide us new set of biomarkers. By using the biomarker set, we can detect early phase of CKD and monitor the progression of disease status. Understanding CKD's importance emphasizes the need for awareness, regular check-ups, and proactive measures to reduce the risk of kidney damage.
