ABSTRACT

COVID-19 vaccine-induced myopericarditis is now commonly encountered in clinical practice. The mainstay of clinical management involves vaccine Spike protein detoxification and colchicine for 12 months or longer. Herein, we present a case of a previously healthy 23-year-old male with autism spectrum disorder who developed COVID-19 vaccine-induced myopericarditis and class II heart failure. He was treated with Spike detoxification, which is the combined use of over-the-counter nattokinase, bromelain, and curcumin, in addition to colchicine. While transient heart failure resolved, his chest discomfort persisted and at times was debilitating. Serial electrocardiograms indicated persistent global ST segment elevation. We describe the successful addition of off-label oral rapamycin to arrest inflammatory processes, extirpate ST elevation, and significantly improve quality of life. We summarize existing research that provided a rationale for the use of rapamycin. Concisely, these include targeting autophagy, mRNA translation, and immune activity modulation. We propose that mTOR inhibitors should be investigated as a potential disease-modifying interim treatment for COVID-19 vaccine induced cardiac injury.

Keywords: COVID-19 vaccination; cardiomyopathy; heart failure; molecular mimicry; rapamycin, drug repurposing.

Introduction

The emergence of the COVID-19 pandemic in late 2019 and early 2020 constituted an unprecedented global public health emergency[1]. In response, vaccine development progressed at an unparalleled pace, with the mRNA-1273 candidate entering clinical trials after only approximately two months of development[2]. The safety profile of SARS-CoV-2 mRNA vaccines remains a topic of substantial scientific debate. There is a growing body of rigorous, methodologically sound, and credible research that points to the concerning severity and frequency of adverse events associated with these vaccines[3]. Particularly, cardiovascular adverse effects constitute a preeminent majority of COVID-19 side effects[4], with 28,641 reports of myopericarditis and 37,966 reports of death in the Vaccine Adverse Event Reporting System (VAERS) at the time of writing[5]. Rose et al. found that COVID-19 vaccination is strongly associated with a serious adverse safety signal of myocarditis, especially in children and young adults resulting in hospitalization and death[6]. Autopsy and population-level studies demonstrate that both clinical and subclinical COVID-19 vaccine-induced myopericarditis can be fatal[7,8]. Accordingly, the development of therapeutic approaches to COVID-19 vaccine-induced myopericarditis is a critical public health objective. Here, we present a case of a previously healthy 23-year-old male with suspected COVID-19 vaccine-induced myopericarditis and heart failure (NYHA II), complicated by pre-existing anxiety and autism. We propose rapamycin as a potential treatment for reducing inflammation and addressing ST elevation.

Case Presentation

A 21-year-old male diagnosed with autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) had received one dose of the Moderna mRNA-1273 COVID-19 vaccine (100 mcg - batch: 061E21A) on November 18th, 2021. Approximately two weeks later, the patient ingested a supratherapeutic dose of atomoxetine (ATX, 200 mg) and dexmethylphenidate (d-MPH, 150 mg, Focalin®). The patient had previously ingested similar doses prior to vaccination, which resulted in expected sympathomimetic effects, including xerostomia, melanoglossia, and anxiety, without any cardiac symptoms. The patient subsequently developed hyperhidrosis, orthostatic intolerance, subjective palpitations, and pitting lower extremity edema (**Figure 1**). These symptoms spontaneously resolved within 24 hours, and the patient returned home without seeking medical attention. However, the patient experienced recurring cardiovascular symptoms, particularly after the ingestion of d-MPH/ATX, prompting discontinuation of psychostimulants and atomoxetine. Throughout the following months, the patient's condition deteriorated. He reported frequent episodes of angina pectoris, dyspnea, palpitations, edema, and fatigue without clear inciting factors. He sought emergency department care multiple times, but his symptoms were consistently attributed to anxiety, likely due to his history of anxiety diagnoses. Nine months after mRNA injection, the patient suffered vaccine failure and contracted COVID-19, managed with nirmatrelvir/ritonavir. The infection was moderate, peaking with a temperature of 104°F, and was followed by several non-SARS-CoV-2 viral upper respiratory infections. Seventeen months after mRNA injection, he contracted COVID-19 again, and while the infection was mild, he soon developed symptoms of heart failure (NYHA Class II), including effort intolerance, dyspnea, orthostatic intolerance, and lower extremity edema (**Figure 2**).

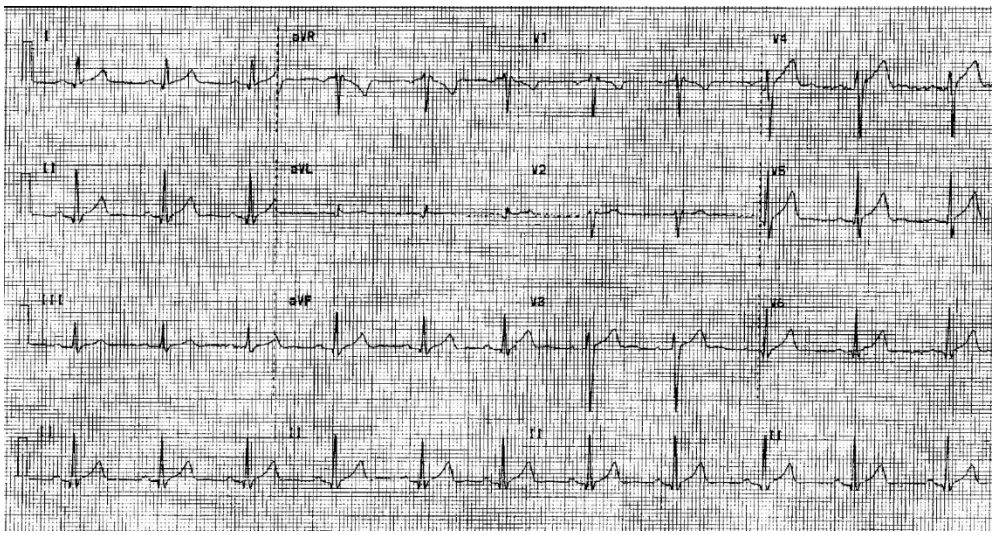
Figure 1: Pitting lower extremity edema observed on Nov. 30th, 2021, approximately 13 days after mRNA-1273 COVID-19 vaccine injection.

Figure 2: Significant lower extremity edema and erythema observed on April 2023, approximately 519 days after mRNA-1273 COVID-19 vaccine injection. Other symptoms included effort intolerance, dyspnea, orthostatic intolerance, and palpitations.

Cardiac evaluation at that time included a 48-hour ambulatory ECG that revealed a heart rate range of 39-205 bpm, with consistent sinus rhythm. Blood pressure was 128/90 mmHg, pulse rate was 62 bpm, and SpO2 100% as clinically measured. Echocardiography showed an ejection fraction of 60%. Electrocardiogram (ECG) at initial clinical encounter indicated diffuse ST elevation (**Figure 3**).

Weight was measured at 172 pounds, with a body mass index of 24.4 kg/m^2. Auscultation revealed no pulmonary crackling or rales. There were no heart murmurs. SARS-CoV-2 S protein IgG quantification was 7058 AU/ml. Based on the presentation, a diagnosis of COVID-19 vaccine-induced myopericarditis was made. A "Spike detoxification protocol" was initiated, consisting of bromelain (500 mg once daily), nattokinase (2,000 FU twice daily), and curcumin (500 mg twice daily)[9]. Given the suspected inflammatory etiology, colchicine (0.6 mg/day) was also prescribed. The patient's response to these treatments was variable, with periods of symptom improvement followed by relapses through the remainder of 2023 and into early 2024. In addition to pharmacological interventions, aerobic exercise (to the extent tolerable) and intermittent fasting were incorporated to maintain cardiac capacity and reduce systemic inflammation.

Figure 3: Electrocardiogram at initial clinical encounter (August 1st, 2023) indicated moderate ST elevation.



6-Month Follow-Up and Successful Treatment with Rapamycin

After six months of treatment for myopericarditis, the patient presented with a blood pressure of 122/80 mmHg, a pulse rate of 75 bpm, and an SpO_2 level of 100%. The ECG revealed persistent ST elevation characteristic of active, ongoing myopericarditis (**Figure 4**). Thoracic ultrasound did not reveal any pericardial effusion, and auscultation was unremarkable for abnormal heart sounds. The patient reported atypical chest pain localized to the seventh left intercostal space. A cardiac MRI with contrast was declined by the patient due to concerns about gadolinium-based contrast agents. SARS-CoV-2 Spike protein IgG quantification had decreased to 2650 AU/ml. Prednisone (20 mg/day) was initiated. The patient experienced improvement in symptoms and resolution of the ST elevation after completing the corticosteroid course. However, due to unfavorable cognitive side effects, the patient chose not to continue corticosteroid therapy, and alternative treatments were explored. Given the patient's reluctance to continue corticosteroids and the persistence of myopericarditis symptoms, rapamycin (1 mg/day per os) was introduced as an alternative therapeutic intervention. The patient's HR, SpO2, and ECG were monitored regularly during treatment. After approximately four weeks of rapamycin administration, ST elevation resolved, and QRS voltage returned to normal (previously showing low voltage). Subjectively, the patient reported durable resolution of symptoms, including chest pain, dyspnea, and effort intolerance. Follow-up labs, including a complete blood count (CBC) and comprehensive metabolic panel (CMP), were performed three months after rapamycin initiation and were unremarkable. A repeat ECG at seven months into rapamycin treatment showed persistent resolution of the ST

elevation (**Figure 5**). The patient's condition had stabilized, and no significant side effects from rapamycin, such as depression of white blood cell counts or inhibition of wound healing, were observed.

Figure 4: Electrocardiogram at 6-month follow-up (February 5th, 2024) revealed extensive ST elevation characteristic of pericarditis.

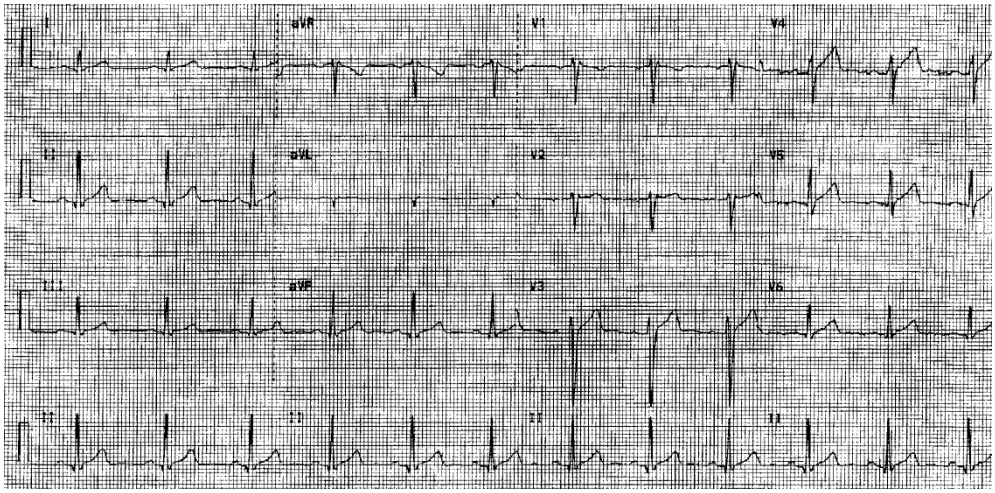


Figure 5: Electrocardiogram at approximately 7 months following initiation of rapamycin treatment (October 16th, 2024) demonstrated complete ST elevation resolution.

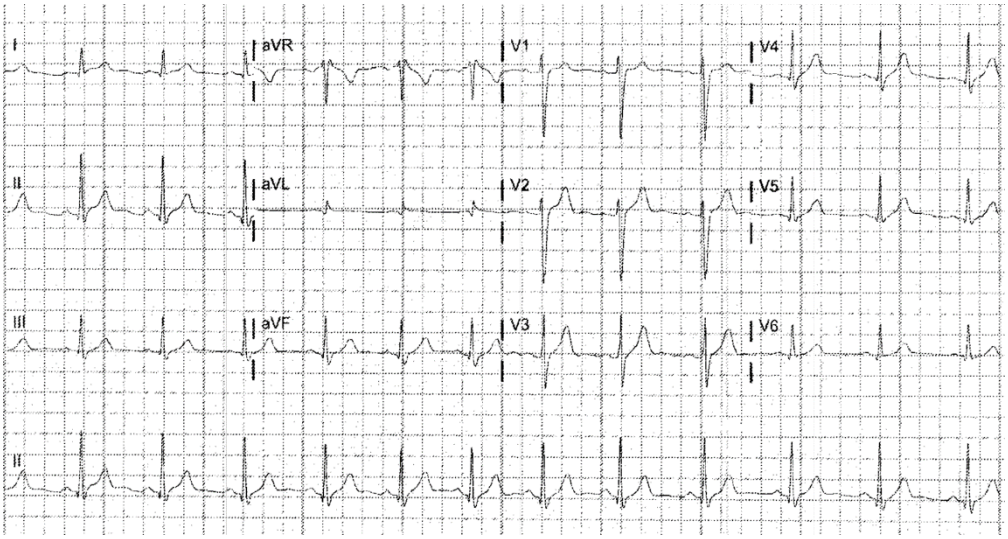

Discussion

In this case report, the patient experienced a near-complete resolution of COVID-19 vaccine-induced myopericarditis and heart failure following standard of care Spike protein detoxification plus colchicine, a course of corticosteroids, and approximately 7 months of treatment with rapamycin. This regimen with Spike protein detoxification interventions[9], including bromelain, curcumin, and nattokinase, and colchicine was designed with the hope of dissolving Spike protein, provision of anti-inflammatory effects, and therapeutic efficacy in resolving COVID-19 vaccine myopericarditis.[10,11] A structured risk stratification approach for future cardiac events post-COVID-19 vaccination was employed to guide the treatment plan (**Figure 6**).[12] The patient's symptomatic improvement was remarkable, with the eventual normalization of electrocardiographic abnormalities and significant relief from effort intolerance, dyspnea, and chest pain. This therapeutic approach appeared to ameliorate the inflammatory processes, reverse the cardiovascular damage, and restore the patient's quality of life.

Figure 6: Risk Stratification Approach for Future Cardiac Arrest after COVID-19 Vaccination.

This case aligns with a growing body of literature indicating that myopericarditis, particularly in younger individuals, has become a significant post-vaccine complication as a result of Spike protein accumulation in cardiac tissues[3,6-9,13-15]. Recurrent COVID-19 infections and booster vaccines can reintroduce Spike protein into circulation, possibly enhancing the risk of myopericarditis[14,15]. Current vaccines appear to have limited efficacy in preventing these reinfections[16], which exacerbates the risk of further Spike-related inflammation. After COVID-19 vaccination, mRNA has been detected in the bloodstream for up to 28 days post-injection[17], and the vaccine-derived, prefusion-stabilized Spike protein persists in circulation for at least six months[18]. This extended presence suggests a considerable window during which myocarditis may develop as a vaccine-related injury. Moreover, cardiac abnormalities have been detected for over a year following the initial diagnosis of COVID-19 vaccine-induced myopericarditis[19], raising concerns about potential long-term effects.

The adverse event profile and safety of COVID-19 vaccines have been found to vary significantly by batch[20-22]. The 'How Bad is My Batch' tool[23], which queries VAERS data, has proven useful in investigating potential vaccine-related deaths and adverse events[24]. In this case, we conducted a batch analysis for the Moderna vaccine received by the patient (batch: 061E21A). The analysis revealed 5 reported deaths, 23 hospitalizations, 19 cases of dyspnea, 17 cases of chest pain or discomfort, 8 cases of tachycardia, 5 cases of palpitations, and 1 case of myocarditis. These reported events from other healthcare providers align closely with the symptoms observed in our case. This batch analysis indicates that cardiovascular adverse events are indeed plausible with the vaccine batch administered in this case, 061E21A.

Rapamycin likely contributed to the resolution of this case through multiple mechanisms, as illustrated in **Figure 7**. We initially explored therapeutic options targeting glycosylation processes. Notably, N-glycosylation inhibition has been shown to impede SARS-CoV-2 replication[25]. Further, alpha-glucosidase inhibition via castanospermine has demonstrated antiviral activity by disrupting glycosylation[26]. However, this approach carries the

risk of inducing ER stress due to protein misfolding, which, combined with the narrow therapeutic window and toxicity of such agents, limits their practical use. Consequently, our therapeutic focus turned to mTOR inhibitors, given that SARS-CoV-2 exploitatively stimulates mTOR signaling to facilitate viral replication[27]. mTOR inhibition has been demonstrated to interrupt SARS-CoV-2 infection[28], and as such, mTOR inhibitors have been proposed for drug repurposing in the treatment of SARS-CoV-2[29]. Additionally, mTOR inhibitors could confer extensive therapeutic effects. mTOR signaling is dysregulated in cardiomyopathy, and mTOR inhibitors have shown promise in managing conditions like hypertrophic cardiomyopathy[30]. Rapamycin, in particular, has demonstrated therapeutic potential in experimental autoimmune myocarditis (EAM), an induced-autoimmunity model produced by vaccinating mice with myosin or actin in combination with an adjuvant[31]. The pathophysiology of EAM mirrors that of vaccine-induced myopericarditis, with both conditions presenting after a post-vaccination latency period. Given that EAM and vaccine-induced myopericarditis share immune self-reactivity mechanisms, rapamycin's immunomodulatory effects likely helped suppress hyperactive immune responses, reducing inflammation and fibrosis in cardiac tissue[31-32]. Of particular relevance is the potential for autoimmunity triggered by molecular mimicry, as prior research has shown significant overlap between SARS-CoV-2 proteins and human cardiac epitopes[33-34]. This molecular mimicry could provoke a self-reactive immune response, particularly targeting cardiac tissue, resulting in myocardial injury. Coordinate pathophysiological mechanisms likely involve RAAS disruptions (the "Spike effect")[35] and aberrant protein accumulation, which are known to contribute to cardiomyopathies[36]. Rapamycin's combined autophagic and immunomodulatory effects make it an ideal candidate for addressing such pathomechanisms[31,37]. As we advanced our consideration of rapamycin's therapeutic potential, we also explored its indirect effects on N-glycosylation. mTOR inhibition downregulates sterol regulatory element-binding protein (SREBP) signaling, which controls the expression of HMG-CoA reductase and regulates the mevalonate pathway[38,39]. This pathway is responsible for producing isoprenoids, including dolichol, which facilitate N-glycosylation. By inhibiting this pathway, rapamycin could help prevent the functional production of Spike proteins from persistent mRNA or genomic inserts, while concurrently reducing pathological RAAS disruption. mTOR inhibition may also reduce Spike protein production by downregulating the cell cycle. mTOR is a key regulator of cell growth and proliferation, and its inhibition leads to cell cycle arrest, particularly in the G1 phase, thereby reducing overall protein synthesis[40]. This reduction in cell proliferation leads to a decrease in global protein production, including Spike proteins. As the cell cycle slows, mTOR inhibition downregulates key proteins involved in mRNA translation such as 4E-BP1 and S6K1, which are essential for initiating protein synthesis[41]. This suppression of translational machinery limits the production of general proteins and possibly the Spike proteins encoded by mRNA vaccines. Importantly, the patient in this case demonstrated a dramatic reduction in Spike protein antibodies during treatment, suggesting that rapamycin, along with adjunctive treatments such as bromelain, curcumin, nattokinase, and colchicine, may have facilitated the clearance of residual Spike protein from the body. This outcome further highlights the potential of mTOR inhibitors, proteolytic enzymes, and anti-inflammatories in the treatment of COVID-19 vaccine-induced myopericarditis. Moreover, the combination of rapamycin's autophagic induction, its capacity to reduce N-glycosylation, and cell cycle downregulation may prevent the production of pathological Spike proteins, offering a multifaceted approach to managing vaccine-induced cardiac injury.

Figure 7: Proposed mechanisms supporting the use of rapamycin in treating COVID-19 vaccine-induced pericarditis.

This case report is inherently limited by its focus on a single patient N of 1 trial. While the patient's positive response to the addition of rapamycin offers encouraging preliminary evidence, it is anecdotal and cannot alone establish causal efficacy. Larger-scale studies and clinical trials are critically needed to confirm these observations and to develop optimized therapeutic protocols for patients facing these emerging and complex conditions. This case presents the challenge of differentiating between the adverse cardiovascular effects of psychostimulants and those induced by COVID-19 vaccination. The safety profile of long-term ADHD treatment with psychostimulants remains unclear, with existing data pointing to the possibility of exacerbating cardiovascular disease[42]. Neuropsychiatric medications may result in more symptomatic syndromes among those with vaccine myopericarditis. Although it is plausible that a stimulant overdose exacerbated the vaccine-induced pathology, the patient had prior tolerance to stimulant use without reported cardiac symptoms.

Conclusion

Base Spike detoxification with nattokinase, bromelain, and curcumin with concurrent colchicine is a reasonable standard of care for COVID-19 vaccine myopericarditis. If symptoms do not resolve, then rapamycin could be considered as empiric adjunctive treatment. Given its mechanism of action and tolerability at low doses, rapamycin should be investigated for the treatment of cardiac or circulatory injuries resulting from COVID-19 vaccination or infection. Although this is a limited case report involving a single patient, it nevertheless provides a hypothetical foundation for possibility that rapamycin may display efficacy in the treatment of COVID-19 vaccine-induced myopericarditis. Therefore, further studies for the treatment of COVID-19 vaccine-induced myopericarditis with rapamycin are warranted, including *in vitro* models, *in silico* models, animal studies, and eventual clinical trials.
